A COMPARISON OF BURN-IN AND BAKE AS SEMICONDUCTOR SCREENING TECHNIQUES
FOR THE NIMBUS SPACECRAFT PROGRAM

Irving J. Ross

ABSTRACT:

21669
This report summarizes and compares the relative effectiveness of high temperature storage (bake) and high temperature operating burn-in as screening techniques for semiconductor devices used in the Nimbus spacecraft program. Data for this report were accumulated from summaries of burn-in and bake screening performed by Nimbus contractors. Results are presented for 162 different types of semiconductor devices, with an overall sample size of 70,300 for an aggregate of 49 million device hours for both screening techniques.

Results indicate that burn-in is superior to bake for every class of semiconductor device and for every manufacturing process used in the fabrication of the devices. Correlation is shown between rated power dissipation and burn-in effectiveness. Statistical significance of the data is evaluated when comparability of types is possible, i.e. where the types were both burned-in and baked.

INTRODUCTION:

Semiconductor device reliability is an essential element in achieving space systems reliability primarily because they are used in very large quantities and form the electronic heart of the systems. The attainment of high reliability in these parts is dependent on two factors:

1. Manufacturing process control which depends to a large extent on the discovery and definition of failure mechanisms present in the design of the devices.

2. Discovery or culling out of defects introduced during device fabrication which affect circuit performance.

It is well established that semiconductor devices exhibit the characteristic of "infant mortality" in which failure mechanism and/or defects in the device manifest themselves in a relatively short time period compared to the expected life of the systems in which they are used. Two methods for screening or weeding out defectives introduced during the manufacturing process from the device population, which have been extensively used, are high temperature storage or bake without power added and power ageing or burn-in which adds power dissipation to temperature and thus more nearly approximates use conditions.

The high temperature storage or bake screen weeds out failure mechanisms or defects which are dependent on temperature alone. Some examples are mechanical stresses of internal lead wire connections to pins induced by thermal expansion at metallic surfaces; poor thermal compression bonds to emitter and base stripes; chemical reactions such as outgassing of surface impurities and changes in the gaseous impurities in the base regions.

Power ageing or burn-in, in addition to the above, detects and culls out failure modes associated with both voltage and current. Those associated with current are due to the formation of hot spots caused by non-uniform junctions, or voids between the semiconductor and the header. Irregularities in the region of the depletion layer leading to punch-through show up as a voltage defect.

Results of studies on 73,000 Minuteman diodes at TRW indicate that use of high temperature with a fixed level of power results in a higher level of failures than does the use of high power at low temperature. The selection of higher ambient temperature assures that the entire device is at an elevated temperature. Thus contaminants which are present may be boiled into the device internal atmosphere which increases the possibility of detecting the placement of contaminants at the device junctions¹. Burn-in at high temperature thus screens out defects dependent on chemical, electrical, and thermal stresses while bake screens out defects dependent only on thermal stresses.

NIMBUS SEMICONDUCTOR PROGRAM

The high temperature storage (bake) program was implemented by all Nimbus subsystem contractors in late 1961, and consisted of subjecting all silicon semiconductors to a high temperature environment, 100°C, for a period of six weeks or 1000 hours. Germanium devices were baked at 80°C for the same period. The devices screened represented a good cross-section of available commercial and military types and the results indicated that only 1.5 percent of baked units failed. A smaller percentage of these failures, however, was catastrophic (i.e., was of the variety which would seriously degrade the Nimbus mission).

In October 1962, recognized authorities in the field of semiconductor manufacturing and device designs were consulted for comments on a power ageing (burn-in) specification². Based on these comments a specification was drawn up which received Nimbus Project approval in November 1962.

The procedure employed elevated ambient temperatures, 100°C for silicon devices and 50°C for germanium for a period of less than two weeks (300 hours). Power was applied to the device in this environment to increase the junction temperature to a nominal 80 percent of its maximum value. Transistor parameters tested were DC current gain, h_{FE} and reverse leakage current I_{CBO} . Pre- and post-burn-in parameter end points were based on military specification formulas, i.e., 20 percent loss in h_{FE} or 100 percent increase in I_{CBO} were criteria for rejection. Voltage, current, and power ratings were not to be exceeded.

The rationale for this specification was as follows:

- a. DC current gain stabilizes when exposed to high temperature after 100 hours.
- b. An elevated temperature power condition tends to accelerate thermal chemical and electrical failure mechanisms. It also reduces the requirement for high voltage or current power supplies in the case of power transistors.
- c. The 300 hour time period was equivalent to that used in the Minuteman program.
- d. The nominal 80 percent of maximum junction temperature was specified as a safety factor to allow for slight variations in thermal resistance from unit to unit.

The specification was transmitted to the OGO Project for information and possible application and was reviewed and endorsed in a memorandum by the Planning Research Corporation, the reliability contractor for the OGO Project, which pointed out that the burn-in requirement used by the Nimbus Project at 80 percent rated junction temperature for two weeks is potentially capable of providing a failure rate reduction for OGO parts. . . by a factor of 2 to 18, the same as Telstar. . .

at significantly less expense and within a minimal time period. "Derated burn-in at expected operating conditions would achieve the same failure rate reduction but would require a burn-in period of 20 weeks."³

All semiconductors screened by Nimbus contractors are listed alpha-numerically in Appendix A. Code letters for device manufacturer, process of manufacture and device power dissipation rating are presented for each device type. The code key is shown on page 15 of this report. In addition, the number of devices screened, number rejected and percent rejected are listed separately for each type and manufacturer and are shown for both screening techniques.

Appendix C represents a regrouping of the alpha-numerical types by class of semiconductor device and by process and power ratings. Subtotals are indicated for process-power groups and for power groups. Totals are shown for classes of devices. The results are summarized in the body of the report.

The data were accumulated from reports furnished by Nimbus contractors and for both screening techniques represents a total of 68 transistor types with a total sample size of 25,420 and a total of 102 diode types with a total sample size of 44,907. Total device hours for transistors was 18 million hours and for diodes was 31 million hours for a combined total of 49 million semiconductor device hours.

RESULTS OF SCREENING BY CLASS OF SEMICONDUCTOR DEVICES

A summary of results of burn-in and bake screening for silicon and germanium transistors is shown in Tables 1 and 2, respectively. Also summarized are the results of screening diodes, Table 3. The reject figures include degradation and catastrophic type failures. Observing the ratio of reject rates of burn-in

to bake (relative effectiveness ratio), it appears that burn-in is more effective than bake for all classes of semiconductor devices.

RESULTS OF SCREENING RELATED TO MANUFACTURING PROCESS

An analysis of the data was made relating relative effectiveness of burn-in and bake to the processes employed in the manufacture of semiconductor devices. These processes are described in the semiconductor technical literature and those used in Nimbus applications form a good cross-section of those used by the semiconductor industry.⁴ Table 4 indicates the results for silicon transistors.

Planar	3	125	25	20.0	2	463	1	.2	100.0

The results indicate that the relative effectiveness ratio favors burn-in over bake for every process utilized for both NPN and PNP silicon transistor type. As expected the reject rate for NPN planar types was the lowest since the planar process minimizes semiconductor surface contamination which is a common failure mechanism in semiconductor devices.

The rejects that did occur on the planar devices were current gain degradation failures. The findings in this Table correspond with the findings of the semiconductor industry in the Minuteman program wherein NPN mesa and NPN planar transistor burn-in results were compared, ⁵ i.e., that planar types had fewer defectives than mesa types. The relative effectiveness ratio (mesa % rejects divided by planar % rejects) was 2.4 as shown in Table 4A.

Comparing NPN and PNP mesa types, the reject rate of PNP types was 1.1 times that for NPN types which tends to support the conjecture of users that shipments of PNP type mesas contain a greater proportion of defectives than NPN mesa types. This conjecture is further supported by the fact that it is easier to fabricate an NPN silicon transistor than a PNP silicon transistor. More NPN silicon types are manufactured than PNP types for this reason which is also reflected in the larger number of NPN types (twice as many) used in the Nimbus subsystems.

Table 5 indicates the results of testing germanium transistors. Here the sample does not reflect a full cross-section of available processes since germanium transistors were utilized only where silicon counterparts were not available at the time the Nimbus subsystems were designed and constructed. The largest number of germanium devices were of the micro-alloy diffused-base type (MADT) used extensively for low energy switching applications in the Nimbus Command clock subsystem.

Alloy Diff	11	2782	81	2.9	1	60	0	-	-

*Type FD 177 excluded

**Germanium Diode

Again the relative effectiveness ratio favors burn-in over bake for each process of diode manufacture. The superiority of the planar process over others is indicated by the relatively low reject rate.

Results of Screening Related to Rated Power

When the data are arranged in terms of the rated power of devices at room temperature, the reject rate increases substantially with high rated power. The classification of power is as follows:

Low Power - Less than 1 watt

Medium Power - Between 1 and 10 watts

High Power - Equal to or greater than 10 watts

Tables 7 and 8 relate screening results as a function of power for NPN and PNP silicon and germanium transistors. Low power types include those used in AF, HF, and low noise and switching applications. Medium power types include differential amplifiers and switching transistors. Table 9 shows effectiveness of burn-in and bake methods for screening of diodes.

TABLE 7
SILICON TRANSISTOR SCREENING EFFECTIVENESS
BY POWER RATING

	Burn-in				Bake				
	No of Types	Units	Rej	%Rej	No of Types	Units	Rej	%Rej	RER
Low	5	580	55	9.5	5	920	22	2.4	4.0
Medium	18	3249	233	7.2	17	5998	137	2.3	3.1
High	4	317	99	31.2	4	569	23	4.0	7.8
Low	10	516	70	13.6	7	829	20	2.4	5.7
Medium	6	1891	311	16.4	7	3950	80	2.0	8.2
High	No high power PNP types used								

The higher reject rates for high power NPN transistors over medium and low power types in burn-in is attributable to the formation of hot spots, a failure mode that is not detectable by high temperature storage.

Percentage of Rejects as a Function of Time

The Nimbus Command Clock contractor measured relevant parameters at 100 hour intervals during the burn-in procedure. These measurements were made at room temperature after stabilization at 55°C. The results are shown in Table 10. Corresponding results in terms of percentage rejects for semiconductors subjected to a 1000 hour bake on identical semiconductor types are shown in Table 11.

TABLE 10

BURN-IN TEST RESULTS

Test Time (Hour)	Transistors (3468) (3416 Tested)		Diodes (10,728 Tested)	
	No. Rej	Cum % Rej	No. Rej	Cum % Rej
100	188	5.41	38	.35
200	57	7.06	14	.48
300	42	8.28	12	.60

TABLE 11

BAKE TEST RESULTS

Test Time (Hours)	Transistors (5086 Tested)		Diodes (1545 Tested)	
	No Rej	%Rej	No Rej	%Rej
1000	66	1.30	14	.09

Figure 1 is a graphical presentation of these results. It would appear from this graph that the cumulative percent rejects is still on the increase after 300 hours of burn-in time, and this is probably true. However data on burn-in test fallout recently reported⁶ which is reproduced in Figure 1 indicates that for conventional diodes and transistors, the fallout of defectives increases by only 1% between 300 and 1000 hours for transistors and by only 0.8% for diodes for the same time interval.

A graph of percent rejects as a function of time is shown in Figure 2. It is quite evident that the "infant mortality" portions of the curves have been passed.

Significance of Results

With one exception, namely, the screening results of the NPN Silicon grown diffused transistor, the differences in the rejection rates of burn-in and bake techniques displayed in Tables 1 through 11 are statistically significant at confidence levels greater than 99 percent. The hypothesis tested was that the percentage of defects found using the 300-hr burn-in method is the same as the percentage of defects found using the 1000-hr bake method. Rejection of this hypothesis was used to support the engineering judgment that a 300-hr burn-in is indeed superior to a 1000-hr bake program.

Demonstration of the superiority of burn-in over bake rests to a large extent on the true percentage of semiconductors which are defective among those submitted for testing. Where the true percent defect is small, large numbers of devices must be submitted for testing using both methods to statistically demonstrate a difference in the effectiveness of the tests in screening out defective devices.

One type of semiconductor which appears to comprise a small percentage of defectives or at least comprise defectives which elude detection using either test method is the rated low power silicon diode FD177. As can be seen from the listing under Silicon Diode, Appendix C, 10035 diodes of this type were burned in for 300 hours with only 41 defectives showing up. A comparable number, 14600 when subjected to 1000 hours of high temperature storage, produced only 4 defectives. These results are statistically significant as indicated in the listing; however, if added in to the totals for all the rated low power diodes they tend to depress the overall percent defectives found in testing diodes of this type which does not appear to be the case. For this reason, the test findings for silicon diodes is summarized with and without the FD177 type included.

Appendix A lists all the semiconductors tested under the Nimbus Program and the number of defects found among the number tested of each type and the kind of test used (i.e., burn-in or bake). It includes those tested under both kinds of tests and those tested using the burn-in method only and those using the bake method only. For the types screened using both methods, the maximum probability Q of noting a difference in the number of defects greater than the observed difference is listed. The equation for computing maximum Q is given in Appendix B.

In the comparison of the percent defectives found by each test method, it was assumed that the probabilities of a defective being submitted for either kind of test are the same. It is realized that this might not be the case since semiconductors of a particular type may have been processed at different times and under different processing conditions.

Thus in selecting what appeared to be the better of the two types of screening, there remains the question of which techniques, if either, was favored by the percent defectives among the devices submitted for test. There is no reason, however, to believe that in this respect either kind of test was inadvertently given an advantage.

Comparison of Screening Effectiveness by Class of Semiconductor Device, Rated Power, and Manufacturing Process

Under the supposition that the same class of devices similar with respect to rated power and made under the same manufacturing process include substantially the same percent defectives on the average, the percentages of devices found to be defective using each kind of test are compared. The comparison of percent defectives between tests for each class, rated power, and manufacturing process are summarized in Appendix C. Again listed with each of these summaries is the maximum probability that burn-in is not superior to bake as evidenced by the sample defect rates. These results likely reflect a more stable situation in which the true percent defects submitted for either test are close. This supposition is based on the fact that the device when categorized by class, rated power, and process are relatively large in number thus tending to more nearly represent defects among manufacturing output over greater manufacturing time spans and under a variety of different manufacturing environments.

Conclusion:

It has been shown that burn-in of semiconductor devices at elevated temperatures for 300 hours is more effective as a screening technique than high temperature storage for longer time periods. This statement holds for all classes of semiconductor devices, processes of manufacture and rated power dissipation. Statistical testing of the hypotheses that bake screening was as effective as the burn-in technique was carried out using computer methods. Results verified that burn-in was a superior technique.

APPENDIX B

PROCEDURE FOR DETERMINING LEVEL OF DIFFERENCE BETWEEN BURN-IN AND BAKE SCREENING RESULTS

Based on engineering considerations, it is asserted that the burn-in screening technique is not inferior to the bake screening technique in culling out defective semiconductors. This assertion rests principally on the fact that certain types of defectives cannot be found by subjecting the semiconductor to a bake program whereas they could be if subjected to a burn-in program.

On the above assertion, the hypothesis is that the bake screening technique is as effective as the burn-in technique, was tested statistically. Since the number of semiconductors subjected to burn-in and bake varies considerably in number by type of semiconductor (this variation requires much in the way of computational effort), it was decided to make the statistical tests using an IBM 1620 computer.

Maximum Probability that Bake Screening Is as Good as Burn-In Screening in Culling Out Defectives

Let

- p = probability that a defective semiconductor by some definition is introduced for test screening.
- π_1 = probability that burn-in screening will detect a defective
- π_2 = probability that bake screening will detect a defective
- n_1 = number of semiconductors (defectives and non-defectives) which are subjected to burn-in
- n_2 = number of semiconductors (defectives and non-defectives) which are subjected to bake
- d_1 = number of defectives found among the n_1 screened using the burn-in method
- d_2 = number of defectives found among the n_2 screened using the bake method.

Testing the hypothesis that $\pi_1 = \pi_2$, we have for the probability Q that d_1 or more defectives are found in burning-in n_1 semiconductors and d_2 or less defectives are found in baking n_2 semiconductors,

$$Q = \sum_{x_1=d_1}^{n_1} \binom{n_1}{x_1} (p\pi)^{x_1} (1-p\pi)^{n_1-x_1} \cdot \sum_{x_2=0}^{d_2} \binom{n_2}{x_2} (p\pi)^{x_2} (1-p\pi)^{n_2-x_2}$$

Q is thus the probability of observing a difference greater than or equal to $d_1 - d_2$ from samples of n_1 and n_2 , respectively. Since p and π cannot be estimated individually from the screening results the value of the product $p\pi$ is selected such that Q , the probability of the observed difference $d_1 - d_2$ being exceeded under the hypothesis $\pi_1 = \pi_2 = \pi$, is maximum. If maximum Q is small, say less than .05, we reject the hypothesis that $\pi_1 = \pi_2$ and accept the alternative; namely, $\pi_1 > \pi_2$; i.e., burn-in is significantly better than bake at a confidence level ≥ 95 percent in screening out defective semiconductors.
